Sujet :

Do Subjective Indicators of Wellbeing Predict an Objective Measure of Health? Are Any Deviations Dependent on Sociodemographic Characteristics?

Description du sujet :

We propose to supervise a student group on a StatApp project to examine deviations between an objective measure of personal health and subjective indicators of wellbeing. The objective is to analyze the deviation between the two and how it varies by sociodemographic characteristics.

The project will use a subset of the UK Household Longitudinal Study (UKHLS, N ? 13,000 participants), which explores the relationship between various social determinants of health, such as education or social class, and a variety of indicators of health and wellbeing. Importantly, the data set includes several self-reported, "subjective" measures of wellbeing, such as self-rated health, life satisfaction, and the General Health Questionnaire, as well as "objective," nurse-collected biomarkers of health, drawn from several physiological systems. This opens the possibility to explore the association of objective and subjective measures of health and wellbeing, as well as how they relate to living conditions.

The objective is, first, to observe how patterns of social determinants of health change according to the choice of measure of health and wellbeing; second, what these changes reflect about the link between health and wellbeing; and third, how the relationship between objective and subjective indicators of health varies across standard sociodemographic determinants (age, cohort, marital status, socioeconomic status, place of residence). The aim is thus to explore how the structure of measures influences observable statistical associations, and to relate this to the scientific debate around the objective and subjective experiences of wellbeing.

For the analysis, students will have to make a brief review of the relevant literature in sociology and public health.

Instruction for the group will be in English.

Données du sujet :

The UK Household Longitudinal Study (UKHLS), known as "Understanding Society," is a large panel study that has followed a representative sample of UK households since 2009, incorporating the long-running British Household Panel Survey. It began with around 40,000 households across England, Scotland, Wales, and Northern Ireland, collecting information on home and family, work and education, health and wellbeing, financial circumstances, and social and political attitudes. In Waves 2-3 (2010-2011), around 20,000 adult participants also received a nurse health visit that collected objective, nurse-measured biomarkers spanning several physiological systems, alongside the survey's self-reported measures of health and wellbeing (self-rated health, life satisfaction, the General Health Questionnaire). This StatApp uses the subset of roughly 13,000 participants with both subjective and objective health measures available. Further description of the data is available at <https://osf.io/u2mhn/>

Modèles envisagés du sujet :

Basic association-based statistics, regression models, and factor and/or cluster analysis. Students will work with standard statistical software: SAS, Stata, or R.
